Communicated by P.M.B. Vitányi

Abstract

We investigate the randomized and quantum communication complexity of the Hamming distance problem, which is to determine if the Hamming distance between two n-bit strings is no less than a threshold d. We prove a quantum lower bound of \(\Omega(d)\) qubits in the general interactive model with shared prior entanglement. We also construct a classical protocol of \(O(d \log d)\) bits in the restricted Simultaneous Message Passing model with public random coins, improving previous protocols of \(O(d^2)\) bits [A.C.-C. Yao, On the power of quantum fingerprinting, in: Proceedings of the 35th Annual ACM Symposium on Theory of Computing, 2003, pp. 77–81], and \(O(d \log n)\) bits [D. Gavinsky, J. Kempe, R. de Wolf, Quantum communication cannot simulate a public coin, quant-ph/0411051, 2004].

Keywords: Computational complexity; Communication complexity; Hamming distance

1. Introduction

Communication complexity was introduced by Yao [17] and has been extensively studied afterward not only for its own intriguing problems, but also for its many applications ranging from circuit lower bounds to data streaming algorithms. We refer the reader to the monograph [12] for an excellent survey.

We recall some basic concepts below. Let \(n\) be an integer and \(X = Y = \{0, 1\}^n\). Let \(f : X \times Y \to \{0, 1\}\) be a Boolean function. Consider the scenario where two parties, Alice and Bob, who know only \(x \in X\) and \(y \in Y\), respectively, communicate interactively with each other to compute \(f(x, y)\). The deterministic communication complexity of \(f\), denoted by \(D(f)\), is defined to be the minimum integer \(k\) such that there is a protocol for computing \(f\) using no more than \(k\) bits of communication on any pair of inputs. The randomized communication complexity of \(f\), denoted by \(R^{pb}(f)\), is similarly defined, with the exception that Alice and Bob can use publicly announced random bits and that they are required to compute \(f(x, y)\) correctly with probability at least \(2/3\). One of the central themes on the classical communication complexity studies is to understand how randomness helps in saving the communication.
A basic finding of Yao [17] is that there are functions $f$ such that $R(f) = \Theta(\log D(f))$. One example is the $\text{EQUALITY}$ problem, which simply checks whether $x = y$.

Later results show that different ways of using randomness result in quite subtle changes on communication complexity. A basic finding in this regard, due to Newman [13], is that public-coin protocols can save at most $O(\log n)$ bits over protocols in which Alice and Bob each toss private (and independent) coins. The situation is, however, dramatically different in the $\text{Simultaneous Message Passing}$ (SMP) model, also introduced by Yao [17], where Alice and Bob each send a message to a third person, who then outputs the outcome of the protocol. Apparently, this is a more restricted model and for any function, the communication complexity in this model is at least that in the general interactive communication model. Denote by $R^\parallel(f)$ and $R^\parallel,\text{pub}(f)$ the communication complexities in the SMP model with private and public random coins, respectively. It is interesting to note that $R^\parallel,\text{pub}(\text{EQUALITY}) = O(1)$ but $R^\parallel(\text{EQUALITY}) = \Theta(\sqrt{n})$ [2,14,5].

Yao also initiated the study of quantum communication complexity [18], where Alice and Bob are equipped with quantum computational power and exchange quantum bits. Allowing an error probability of no more than $1/3$ in the interactive model, the resulting communication complexity is the quantum communication complexity of $f$, denoted by $Q(f)$. If the two parties are allowed to share prior quantum entanglement, the quantum analogy of randomness, the communication complexity is denoted by $Q^*(f)$. Similarly, the quantum communication complexities in the SMP model are denoted by $Q^\parallel$ and $Q^\parallel,\text{pub}$, depending on whether prior entanglement is shared. The following relations among the measures are easy to observe.

$$Q^*(f) \leq R^\text{pub}(f) \leq R^\parallel,\text{pub}(f).$$  \hspace{1cm} (1)

Two very interesting problems in both communication models are the power of quantumness, i.e., determining the biggest gap between quantum and randomized communication complexities, and the power of shared entanglement, i.e., determining the biggest gap between quantum communication complexities with and without shared entanglement. An important result for the first problem by Buhrman et al. [7] is $Q^\parallel(\text{EQUALITY}) = O(\log n)$, an exponential saving compared to the randomized counterpart result $R^\parallel(\text{EQUALITY}) = \Theta(\sqrt{n})$ mentioned above. This exponential separation is generalized by Yao [19], showing that $R^\parallel,\text{pub}(f) = \text{constant}$ implies $Q^\parallel(f) = O(\log n)$. As an application, Yao considered the $\text{HAMMING DISTANCE}$ problem defined below. For any $x, y \in \{0,1\}^n$, the Hamming weight of $x$, denoted by $|x|$, is the number of 1’s in $x$, and the Hamming distance of $x$ and $y$ is $|x \oplus y|$, with “$\oplus$” being bit-wise XOR.

**Definition 1.1.** For $1 \leq d \leq n$, the $d$-$\text{HAMMING DISTANCE}$ problem is to compute the following Boolean function $\text{HAM}_{n,d} : \{0,1\}^n \times \{0,1\}^n \rightarrow \{0,1\}$, with $\text{HAM}(x, y) = 1$ if and only if $|x \oplus y| > d$.

**Lemma 1.2.** (Yao [19].) $R^\parallel,\text{pub}(\text{HAM}_{n,d}) = O(d^2)$.

In a recent paper [10], Gavinsky et al. gave another classical protocol, which is an improvement over Yao’s when $d \gg \log n$.

**Lemma 1.3.** (Gavinsky et al. [10].) $R^\parallel,\text{pub}(\text{HAM}_{n,d}) = O(d \log n)$.

In this paper, we observe a lower bound for $Q^*(\text{HAM}_{n,d})$, which is also a lower bound for $R^\parallel,\text{pub}(\text{HAM}_{n,d})$ according to Eq. (1).

Notice that $\text{HAM}(x, y) = n - \text{HAM}(x, \bar{y})$, where $\bar{y} \stackrel{\text{def}}{=} 11 \cdots 1 \oplus y$. Therefore

$Q^*(\text{HAM}_{n,d}) = Q^*(\text{HAM}_{n,n-d})$

and we need only consider the case $d \leq n/2$.

**Proposition 1.4.** For any $d \leq n/2$, $Q^*(\text{HAM}_{n,d}) = \Omega(d)$.

We then construct a public-coin randomized SMP protocol that almost matches the lower bound and improves both of the above protocols.

**Theorem 1.5.** $R^\parallel,\text{pub}(\text{HAM}_{n,d}) = O(d \log d)$.

We shall prove the above two results in the following sections. Finally we discuss open problems and a plausible approach for closing the gap.

**Other related work.** Ambainis et al. [3] considered the error-free communication complexity, and proved that any error-free quantum protocol for the Hamming Distance problem requires at least $n - 2$ qubits of communication in the interactive model, for any $d \leq n - 1$. Feigenbaum et al. [9] started the secure multiparty approximate computation of the Hamming distance.
2. Lower bound of the quantum communication complexity of the Hamming distance problem

For proving the lower bound, we restrict HAM_{n,d} on those pairs of inputs with equal Hamming distance. More specifically, for an integer $k$, $1 \leq k \leq n$, define $X_k = Y_k \overset{\text{def}}{=} \{x: x \in \{0,1\}^n, |x| = k\}$. Let HAM_{n,k,d} : $X_k \times Y_k \rightarrow \{0,1\}$ be the restriction of HAM_{n,d} on $X_k \times Y_k$.

Before proving Proposition 1.4, we briefly introduce some related results. Let $x, y \in \{0,1\}^n$. The DISJOINTNESS problem is to compute the following Boolean function DISJ_n : $\{0,1\}^n \times \{0,1\}^n \rightarrow \{0,1\}$, DISJ_n(x,y) = 1 if and only if there exists an integer $i$, $1 \leq i \leq n$, so that $x_i = y_i = 1$. It is known that $R(\text{DISJ}_n) = \Theta(n)$ [11,15], and $Q^*(\text{DISJ}_n) = \Theta(\sqrt{n})$ [16,14].

We shall use an important lemma in Razborov [16], which is more general than his remarkable lower bound on quantum communication complexity of DISJOINTNESS. Here we may abuse the notation by viewing $x \in \{0,1\}^n$ as the set $\{i \in [n]: x_i = 1\}$.

Lemma 2.1. (Razborov [16].) Suppose $k \leq n/4$ and $l \leq k/4$. Let $D : [k] \rightarrow \{0,1\}$ be any Boolean predicate such that $D(l) \neq D(l-1)$. Let $f_{n,k,D} : X_k \times Y_k \rightarrow \{0,1\}$ be such that $f_{n,k,D}(x,y) \overset{\text{def}}{=} D(|x \cap y|)$. Then $Q^*(f_{n,k,D}) = Q^*(\text{HAM}_{n,k,d})$.

Proof of Proposition 1.4. Consider $D$ in Lemma 2.1 such that $D(t) = 1$ if and only if $t < l$. For any $x, y \in X_k$, we have $|x \cap y| = k - \text{HAM}(x,y)/2$. Let $l = k - d/2$, then $k - \text{HAM}(x,y)/2 < l$ if and only if $\text{HAM}(x,y) > d$. Therefore, $D(|x \cap y|) = 1$ if and only if $\text{HAM}(x,y) > d$. This implies that $f_{n,k,D}$ and HAM_{n,k,d} are actually the same function, and thus $Q^*(f_{n,k,D}) = Q^*(\text{HAM}_{n,k,d})$.

To use Lemma 2.1, the following two constraints on $k$ and $l$ need to be satisfied: $k \leq n/4$ and $l \leq k/4$. When $d \leq 3n/8$, let $k = 2d/3 \leq n/4$, then $l = 2d/3 - d/2 = d/6 \leq n/16$. Both requirements for $k$ and $l$ are satisfied. So applying Lemma 2.1, we get $Q^*(\text{HAM}_{n,k,d}) = Q^*(f_{n,k,D}) = Q^*(\text{HAM}_{n,k,d}) = \Omega(\sqrt{kl}) = \Omega(d)$.

For $3n/8 < d \leq n/2$, it is reduced to the above case ($d \leq 3n/8$) rather than Lemma 2.1. Let $m = \lceil 8d/5 - 3n/5 \rceil$. Fix first $m$ bits in $x$ to be all 1’s, and use $x'$ to denote $x_{m+1} \ldots x_n$. Similarly, fix first $m$ bits of $y$ to be all 0’s, and use $y'$ to denote $y_{m+1} \ldots y_n$. Put $n' = n - m, k' = n'/4, \text{and } d' = d - m$. Then HAM(x,y) = HAM(x',y') + m and $Q^*(\text{HAM}_{n,d}) = Q^*(\text{HAM}_{n',d'})(x',y')$. It is easy to verify that $d' \leq 3n/8$ and $d' = \Omega(d)$. Employing the result of the case that $d \leq 3n/8$, we have $Q^*(\text{HAM}_{n',k',d'}) = \Omega(d')$. Thus $Q^*(\text{HAM}_{n,d}) = Q^*(\text{HAM}_{n',d'}) = \Omega(d') = \Omega(d)$. \hfill $\square$

3. Upper bound of the classical communication complexity of the Hamming distance problem

To prove Theorem 1.5, we reduce the HAM_{n,d} problem to HAM_{16d^2,d} problem by the following lemma.

Lemma 3.1.

$R^{\text{ill.}}(\text{HAM}_{n,d}) = O(R^{\text{ill.}}(\text{HAM}_{16d^2,d}))$.

Note that Theorem 1.5 immediately follows from Lemma 3.1 because by Lemma 1.3, $R^{\text{ill.}}(\text{HAM}_{n,d}) = O(d \log n)$, thus $R^{\text{ill.}}(\text{HAM}_{16d^2,d}) = O(d \log d^2) = O(d \log d)$. Now by Lemma 3.1, we have $R^{\text{ill.}}(\text{HAM}_{n,d}) = O(d \log d)$.

So in what follows, we shall prove Lemma 3.1. Define a partial function HAM_{n,d/2d}(x,y) with domain $\{(x,y): x, y \in \{0,1\}^n, |x \oplus y| \text{ is either less than } d \text{ or at least } 2d\}$ as follows:

$$
\text{HAM}_{n,d/2d}(x,y) = \begin{cases} 
0 & \text{if } \text{HAM}(x,y) \leq d, \\
1 & \text{if } \text{HAM}(x,y) > 2d.
\end{cases}
$$

Then

Lemma 3.2.

$R^{\text{ill.}}(\text{HAM}_{n,d/2d}) = O(1)$.

Proof. We revise Yao’s protocol [19] to design an O(1) protocol for HAM_{n,d/2d}. Assume the Hamming distance between $x$ and $y$ is $k$. Alice and Bob share some random public string, which consists of a sequence of $yn$ ($y$ is some constant to be determined later) random bits, each of which is generated independently with probability $p = 1/(2d)$ of being 1. Denote this string by $z_1, z_2, \ldots, z_y$, each of length $n$. Party $A$ sends the string $a = a_1a_2\ldots a_y$ to the referee, where $a_i = x \cdot z_i \mod 2$. Party $B$ sends the string $b = b_1b_2\ldots b_y$ to the referee, where $b_i = y \cdot z_i \mod 2$. The referee announces $\text{HAM}_{n,d/2d}(x,y) = 1$ if and only if the Hamming distance between $a$ and $b$ is more than $m = (1/2 - q)\gamma$ where $q = ((1 - 1/d)^d + (1 - 1/d)^{2d})/4$.

Now we prove the above protocol is correct with probability at least 49/50. Let $c_i = a_i \oplus b_i$. Notice that the Hamming distance between $a$ and $b$ is the number of 1’s in $c = c_1c_2\ldots c_y$. We need the following lemma by Yao [19]:
Lemma 3.3. Assume that the Hamming distance between $x$ and $y$ is $k$. Given $c$ as defined above, each $c_i$ is an independent random variable with probability $a_k$ of being 1, where $a_k = 1/2 - 1/(1 - 1/d)^k$.

Since $a_k$ is an increasing function over $k$, to separate $k \leq d$ from $k > 2d$, it would be sufficient to discriminate the two cases that $k = d$ and $k = 2d$. Let $N_k$ be a random variable denoting the number of 1’s in $c$, and $E(N_k)$ and $\sigma(N_k)$ denote corresponding expectation and standard deviation, respectively. Then we have $E(N_k) = a_k \gamma$, and $\sigma(N_k) \leq (a_k \gamma)^{1/2}$. Thus $E(N_{2d}) - E(N_d) = \gamma (a_{2d} - a_d) = \frac{1}{2} \gamma (1 - \frac{1}{2} d^2 (1 - \frac{1}{2} \gamma d^2)) \geq \frac{1}{8} \gamma$. Let $\gamma = 20000$, then $E(N_{2d}) - E(N_d) \geq 2500$, while $\sigma(N_d), \sigma(N_{2d}) < (\frac{1}{2} \gamma)^{1/2} = 100$. The cutoff point in the protocol is the middle of $E(N_d)$ and $E(N_{2d})$. By Chebyshev Inequality, with probability of at most $1/100$, $|N_d - E(N_d)| > 10 \sigma(N_d) = 1000$. So does $N_{2d}$. Thus with probability of at least 49/50, the number of 1’s in $c$ being more than cutoff point implies $k > 2d$ and vice versa. Therefore, $O(y)$ communication is sufficient to discriminate the case $\text{HAM}(x, y) > 2d$ and $\text{HAM}(x, y) \leq d$ with error probability of at most 1/50. □

The following fact is also useful

Fact 1. If 2d balls are randomly thrown into 16d² buckets, then with probability of at least 7/8, each bucket has at most one ball.

Proof. There are $\frac{2d^2}{16d^2}$ pairs of balls. The probability of one specific pair of balls falling into the same bucket is $\frac{1}{16d^2} \cdot \frac{1}{16d^2} = \frac{1}{16d^2}$. Thus the probability of having a pair of balls in the same bucket is upper bounded by $\frac{1}{16d^2} \cdot \left(\frac{2d^2}{2}\right) < 1/8$. Thus Fact 1 holds. □

Now we are ready to prove Lemma 3.1.

Proof of Lemma 3.1. If $16d^2 \geq n$, the lemma is obviously true by appending 0’s to $x$ and $y$.

If $16d^2 < n$, suppose we already have a protocol $P_1$ of $C$ communication to distinguish the cases $|x \oplus y| \leq d$ and $d < |x \oplus y| \leq 2d$ with error probability at most 1/8. Then we can have a protocol of $C + O(1)$ communication for $\text{HAM}_{n,d}$ with error probability at most 1/4. Actually, by repeating the protocol for $\text{HAM}_{n,d|2d}(x, y)$ several times, we can have a protocol $P_2$ of $O(1)$ communication to distinguish the cases $|x \oplus y| \leq d$ and $|x \oplus y| > 2d$ with error probability at most 1/8. Now the whole protocol $P$ is as follows. Alice sends the concatenation of $m_{A,1}$ and $m_{A,2}$, which are her messages when she runs $P_1$ and $P_2$, respectively. So does Bob send the concatenation of his two corresponding messages $m_{B,1}$ and $m_{B,2}$. The referee then runs protocol $P_i$ on $(m_{A,i}, m_{B,i})$ and gets the results $r_i$. The referee now announces $|x \oplus y| \leq d$ if and only if both $r_1$ and $r_2$ say $|x \oplus y| \leq d$.

It is easy to see that the protocol is correct. If $|x \oplus y| \leq d$, then both protocols announce so with probability at least 7/8, and thus $P$ says so with probability at least 3/4. If $|x \oplus y| > d$, then one of the protocols gets the correct range of $|x \oplus y|$ with probability at least 7/8, and thus $P$ announces $|x \oplus y| > d$ with probability at least 7/8 too.

Now it remains to design a protocol of $O(R_{\|\text{pub}}(\text{HAM}_{16d^2,d}))$ communication to distinguish $|x \oplus y| \leq d$ and $d < |x \oplus y| \leq 2d$. First we assume that $n$ is divisible by $16d^2$, otherwise we pad some 0’s to the end of $x$ and $y$. Using the public random bits, Alice divides $x$ randomly into $16d^2$ parts evenly, Bob also divides $y$ correspondingly. Let $A_i, B_i (1 \leq i \leq 16d^2)$ denote corresponding parts of $x, y$. By Fact 1, with probability at least 7/8, each pair $A_i, B_i$ would contain at most one bit on which $x$ and $y$ differ. Therefore, the Hamming distance of $A_i$ and $B_i$ would be either 0 or 1, i.e., the Hamming distance of $A_i$ and $B_i$ equals the parity of $A_i \oplus B_i$, which is further equal to $\text{PARITY}(A_i) \oplus \text{PARITY}(B_i)$. Let $a_i$ denote the parity of $A_i$, $b_i$ denote the parity bit of $B_i$, and let $a = a_1a_2 \ldots a_{16d^2}, b = b_1b_2 \ldots b_{16d^2}$. Then $\text{HAM}_{16d^2,d}(a, b) = \text{HAM}_{n,d}(x, y)$ with probability at least 7/8. So we run the best protocol for $\text{HAM}_{16d^2,d}$ on the input $(a, b)$, and use the answer to distinguish $|x \oplus y| \leq d$ and $d < |x \oplus y| \leq 2d$. □

4. Discussion

We conjecture that our quantum lower bound in Lemma 1.4 is tight. It seems plausible to remove the $O(\log d)$ factor in our upper bound. Recently, Aaronson and Ambainis [1] sharpened the upper bound of the Set Disjointness problem from $O(\sqrt{n} \log n)$ to $O(\sqrt{n})$ using quantum local search instead of Grover’s search. In their method, it takes only constant communication qubits to synchronize two parties and simulate each quantum query. From Yao’s protocol [19], one can easily derive an $O(d \log d)$ two way interactive quantum communication protocol using quantum counting [6] and the connection between quantum query and communication [8]. Methods similar to [1] might help to remove the $O(\log d)$ factor in this upper bound.
Acknowledgement

We thank Alexei Kitaev for suggesting the relation of the HAMMING DISTANCE problem and the DISJOINTNESS problem, Ronald de Wolf for pointing out a mistake in our earlier draft, Jialin Zhang for suggesting to remove the $O(d \log d)$ term in Lemma 3.1 in our earlier draft and anonymous reviewers for helping us improve the presentation of this paper.
