Abstract—Rival Penalized Competitive Learning (RPCL) can automatically select the number of clusters during learning via penalizing the rival in competition. The original adaptive RPCL algorithm is proposed for clusters of spherical shapes and its performance will degenerate considerably when the clusters are of complicated shapes. In this paper, adaptive RPCL learning has been extended to solve this problem via the finite mixture modeling and multi-sets modeling, respectively. Moreover, two general competition types are suggested, called Type A and Type B. The Type B RPCL with both the finite mixture modeling and multi-sets modeling includes the original RPCL as a special case. The experiments have shown that both Type A and Type B RPCL work well and improved the original RPCL considerably for clusters of complicated shapes and strong overlapping. Moreover, the Type B RPCL is the best in automatic selection of correct number of clusters.

Keywords—Clustering Analysis, Rival Penalized, Competitive Learning, Non-spherical Shape.

1. Introduction

Given a data set $D_x = \{x_i\}_{i=1}^N$, the task of partitioning $D_x$ into $k$ clusters is a classical problem in the literature of statistics and pattern recognition, usually called cluster analysis [1], [2], [3]. A well known formulation of this task is to use $k$ vectors $\{m_j^*\}_{j=1}^k$, called centers or code-vectors to represent the $k$ clusters such that a sample $x_i$ is classified into the $y$-th cluster when $I(y|x_i) = 1$, according to:

$$I(y|x_i) = \begin{cases} 1, & \text{if } y = \arg \min_j \|x_i - m_j\|^2 \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

with $\{m_j^*\}_{j=1}^k$ obtained by

$$\min_{\{m_j\}_{j=1}^k} E_{MSE}, \quad E_{MSE} = \frac{1}{N} \sum_{j=1}^k \sum_{i=1}^N I(y|x_i)\|x_i - m_j\|^2. \quad (2)$$

This formulation is called the Mean Square Error (MSE) clustering analysis or vector quantization. It is typically implemented by the well known $k$-means algorithm or the LBG algorithm, which is a two-step iterative procedure, starting from an initial guess on either $\{m_j\}_{j=1}^k$ or $\{I(y|x_i)\}_{i=1}^N$:

**Step 1:** update $\{I(y|x_i)\}_{i=1}^N$ by eq.(1), get

$$\alpha_j = \frac{1}{N} \sum_{i=1}^N I(y|x_i),$$

**Step 2:** update $m_j = \frac{1}{\alpha_j N} \sum_{i=1}^N I(y|x_i)x_i$.

Equivalently, many of the so called competitive learning algorithms in the literature of neural networks can be regarded as adaptive variants of the above algorithm for MSE clustering (e.g., see the Ref. List in [11]).

The algorithms in this formulation all have two serious limitations. The first one is that the number $k$ of clusters must be pre-known and fixed. $E_{MSE}$ monotonically decreases with increasing $k$, and thus cannot detect a correct $k$. However, a bad estimate of $k$ can cause serious problems as stated in [11]. To the best of our knowledge, the selection of a correct $k$ remains an important open problem. It is usually tackled by some heuristic techniques, e.g., ISODATA [1], [2], [3], and Rival Penalized Competitive Learning (RPCL) [11]. The other limitation is that the formulation implies that samples come from a mixture of $k$ Gaussian densities with equal proportion and equal variance $\sigma^2 I$. This special case deviates from many practical situations. In the literature, the so called Mahalanobis distance clustering or elliptic clustering attempts to overcome this limitation.

In this paper, the original adaptive RPCL learning has been extended to clustering of data clusters with complicated shapes, via the finite mixture modeling [6], [7] and multi-sets modeling [10], respectively. Moreover, two general competition types are suggested, called Type A and Type B. The experiments will be made to demonstrate the success of the proposed extensions.
2. Adaptive RPCL Learning with Finite Mixture Modeling

Rival Penalized Competitive Learning (RPCL) is a heuristic competitive learning algorithm proposed for clustering with a favorable feature that it can drive away extra neurons during learning with automatic number selection[11]. The key idea of RPCL is that for each input \( x_i \) not only the winner is learned to approach \( x_i \), but also the second winner (rival) is de-learned away from \( x_i \) for a bit. That is,

\[
m_{c}^{(t+1)} = m_{c}^{(t)} + \gamma_{c}(x_i - m_{c}), \\
m_{r}^{(t+1)} = m_{r}^{(t)} - \gamma_{r}(x_i - m_{r}), \\
m_{j}^{(t+1)} = m_{j}^{(t)}, \quad \text{for } j \neq c, \ j \neq r,
\]

with \( \gamma_{c} > \gamma_{r} \) and \( \gamma_{r} \) being the frequency that \( m_{j} \) wins the competition up to now. Many experiments have shown that RPCL works well although there is no theoretical justification. In Xu(1995a), via an incremental EM algorithm, we have justified the RPCL’s heuristic use of de-learning together with learning[9].

Two types of general forms of RPCL are proposed in [8] based on the following finite mixture:

\[
P(x) = \sum_{j=1}^{k} \alpha_{j} P_{j}(x, \theta_{j}),
\]

That is, we consider two types of competitions:

**Competition Type A (MAP-RPCL):**

\[
c = \arg \max_{j} \alpha_{j} P_{j}(x, \theta_{j}), \\
r = \arg \max_{j \neq c} \alpha_{j} P_{j}(x, \theta_{j}).
\]

**Competition Type B:**

\[
c = \arg \max_{j} \alpha_{j} \ln P_{j}(x, \theta_{j}), \\
r = \arg \max_{j \neq c} \alpha_{j} \ln P_{j}(x, \theta_{j}).
\]

Then, for each input \( x \) we update parameters by

\[
\theta_{c}^{(t+1)} = \theta_{c}^{(t)} + \gamma_{c} \frac{\partial \log P(x, \theta_{c})}{\partial \theta_{c}^{(t)}}, \\
\theta_{r}^{(t+1)} = \theta_{r}^{(t)} - \gamma_{r} \frac{\partial \log P(x, \theta_{r})}{\partial \theta_{r}^{(t)}}, \\
\theta_{j}^{(t+1)} = \theta_{j}^{(t)}, \quad j \neq c, \ j \neq r.
\]

Type A is equivalent to \( c = \arg \max_{j} \ P(j|x) \) because \( P(j|x) = \alpha_{j} P_{j}(x, \theta_{j})/P(x) \), which is usually called Bayesian or Maximum Posterior (MAP) Decision, so we call the corresponding RPCL by MAP-RPCL. Also, \( \alpha_{c} P_{c}(x, \theta_{c}) \) is the largest component in the mixture density \( P(x) \), which represents the average likelihood.

For Type B, \( \alpha_{c} \ln P_{c}(x, \theta_{c}) \) is the largest component in the mixture log-likelihood function, which represents the average log-likelihood. The two types become the same when \( \alpha_{j} \) is equal for each \( j \). They are different in accounting the effect of \( \alpha_{j} \), which can be simply approximated by \( f_{j} \)--the frequency that \( m_{j} \) wins the competition up to now. For a smaller \( \alpha_{j} \), the neuron’s competitive ability becomes weaker in Type A, but strong in Type B. In the other word, Type B is more conscience.

When \( P_{j}(x, \theta_{j}) \) is a gaussian \( G(x, m_{j}, \Sigma_{j}) \), we have:

**Competition Type A (MAP-RPCL):**

\[
c = \arg \min_{j} d_{j}, \\
r = \arg \max_{j \neq c} d_{j}, \\
d_{j} = (x - m_{j})\Sigma_{j}^{-1}(x - m_{j}) + \log |\Sigma_{j}| - 2 \log \alpha(\delta)
\]

**Competition Type B:**

\[
c = \arg \min_{j} d_{j}, \\
r = \arg \max_{j \neq c} d_{j}, \\
d_{j} = \alpha_{j}[(x - m_{j})\Sigma_{j}^{-1}(x - m_{j}) + \log |\Sigma_{j}|]
\]

and from eq.(7) the updating on parameters \( m_{j} \) becomes exactly eq.(3). We can let the updating for \( \alpha_{j} \) be simply approximated by \( f_{j} \)--the frequency that \( m_{j} \) wins the competition up to now. In the special case that \( \Sigma_{j} = I \) of spherical shape. This Type B returns to exactly the original RPCL. In the general case for \( \Sigma_{j} \), we need to update it too, for which a batch way algorithm is suggested in [8].

In this paper, we propose the following adaptive updating for

\[
\Sigma_{c}^{(t+1)} = (1 - \gamma_{c})\Sigma_{c}^{(t)} + \gamma_{c}(x_{i} - m_{c})(x_{i} - m_{c})^{T}, \\
\Sigma_{y}^{(t+1)} = \Sigma_{y}^{(t)}, \quad \text{for } \ y \neq c.
\]

3. Adaptive RPCL Learning with Multi-Sets Modeling

Given \( X = \{x_{i}\}_{i=1}^{N} \), we restate the multisets modeling learning [10] for the problem of parametric clustering in a general paradigm that consists of two sub-tasks. One is partitioning \( X \) into \( K \) sets (or called clusters) \( C_{1}, \cdots, C_{K} \). The second is to model each set \( C_{j} \) by a parametric expression, denoted by \( C_{j}(\theta_{j}) \) or simply \( \theta_{j} \). Suppose that the error or distortion of using this model to represent a sample \( x_{i} \) is denoted by
\( \epsilon(x_i, \theta_j) \geq 0 \), our purpose is to assign each sample \( x_i \) into a \( C_j \) according to an indicator \( I(j|x_i) = 1 \) if \( C_j \) wins the following competition

\[
I(y|x_i) = \begin{cases} 
1, & \text{if } y = \arg \min_j \epsilon(x_i, \theta_j) \\
0, & \text{otherwise}
\end{cases}
\]  

such that the parameters \( \{\theta_j\}_{j=1}^K \) are obtained by

\[
\min_{\{\theta_j\}_{j=1}^K} \sum_{j=1}^K E(j, \theta_j),
\]

\[
E(j, \theta_j) = \frac{1}{N} \sum_{i=1}^N I(k|x_i)\epsilon(x_i, \theta_j).
\]

In general, again we propose to solve this problem by an extension of RPCI algorithm. That is, get the winner by \( k = \arg \min_j f_j \epsilon(x_i, \theta_j) \) with \( f_j \) being the frequency that \( C_j \) wins in the past, and get the rival by \( r = \arg \min_{j \neq k} f_j \epsilon(x_i, \theta_j) \); Then, update:

\[
\theta^{(t+1)}_{e} = \theta^{(t)}_{e} - \gamma_{e} \frac{\partial \epsilon(e, \theta_{e})}{\partial \theta^{(t)}_{e}},
\]

\[
\theta^{(t+1)}_{r} = \theta^{(t)}_{r} + \gamma_{r} \frac{\partial \epsilon(r, \theta_{r})}{\partial \theta^{(t)}_{r}},
\]

\[
\theta^{(t+1)}_{j} = \theta^{(t)}_{j}, \quad y \neq c, \quad y \neq r.
\]

This Multi-Set Modeling paradigm actually unifies various types of clustering via using different parametric models for \( C_j \) and different measures for \( \epsilon(x_i, \theta_j) \):

**Type 1. Conventional Mean Square Error (MSE) Clustering (having linear boundaries between clusters):** Each \( C_j \) is of spherical shape in equal scale and the task is to locate \( C_j \)'s center point. Thus, we have \( \theta_j = m_j \) and the error measure is \( \epsilon(x_i, \theta_j) = ||x_i - m_j||^2 \). This kind of clustering has been widely studied already. In fact, the above algorithms in this case reduce to the case of eq.(1) and eq.(2) by the K-means algorithm eq.(3) or the original RPCI algorithm eq.(3).

**Type 2. Weighted MSE (or called Mahalanobis distance) Clustering (having quadratic boundaries between clusters):** \( C_j \) is of elliptic shape, with its location given by a point \( m_j \) and its shape + orientation by a positive definite matrix \( \Sigma_j \). That is, \( \theta_j = \{m_j, \Sigma_j\} \). The error \( \epsilon(x_i, \theta_j) = (x_i - m_j)^T \Sigma_j^{-1} (x_i - m_j) \) is the Mahalanobis distance between \( x_i \) and \( m_j \). When \( \Sigma_j = \sigma_j^2 I \), every cluster is still of spherical shape but now can be of different scale factor \( \sigma_j \). When \( \Sigma_j \) is a general positive diagonal matrix, every cluster is a canonical ellipse. Furthermore, when \( \Sigma_j \) is general positive definite symmetric matrix, every cluster is a general ellipse in any orientation and scale.

If \( \Sigma_j \) is known in advance, its implementation is the same as Type 1 except for using \( \epsilon(x_i, \theta_j) = (x_i - m_j)^T \Sigma_j^{-1} (x_i - m_j) \) to replace \( \epsilon(x_i, \theta_j) = ||x_i - m_j||^2 \) in competition. When \( \Sigma_j \) is unknown, we can use eq.(10) for its updating.

**Type 3. Local Least Mean Square Error Reconstruction (LMSE) or Local PCA Clustering (having quadratic boundaries between clusters):** \( C_j \) is a line passing through a point \( m_j \) and along the direction \( w_j - m_j \) which is the principal axis of \( C_j \) with maximum variance. Thus, \( \theta_j = \{m_j, w_j\} \). The error \( \epsilon(x_i, \theta_j) = ||(x_i - m_j) - (w_j - m_j)^T (x_i - m_j)||^2 \) is the Square Reconstruction Error \( ||x_i - \tilde{x}_j||^2 \) by the orthogonal project \( \tilde{x}_j = m_j + (w_j - m_j)^T (x_i - m_j) \) of \( x_i \) to \( m_j \) on the principal direction \( w_j - m_j \). An equivalent measure can also be \( \epsilon(x_i, \theta_j) = ||x_i - m_j||^2 \) – \( ||(w_j - m_j)^T (x_i - m_j)||^2 \).

Since the solution of this clustering is that \( m_j \) is the mean of \( C_j \) and \( w_j - m_j \) is the principal axis of \( C_j \) with \( \Sigma_j (w_j - m_j) = \lambda_{max} (w_j - m_j) \). One adaptive way for solving it is to cooperate in Oja rule [4] and its anti-hebbian variant[12]:

\[
\begin{align*}
\mu_{e}^{(t+1)} &= \mu_{e}^{(t)} + \gamma_{e} (x_i - \mu_{e}^{(t)}) \\
y_{e}(t+1) &= (w_{e}^{(t)} - m_{e}^{(t+1)}) \\
w_{e}^{(t+1)} &= w_{e}^{(t)} + \gamma_{e} y_{e}[(x_i - m_{e}^{(t+1)}) - y_{e}(w_{e}^{(t)} - m_{e}^{(t+1)})] \\
m_{e}^{(t+1)} &= m_{e}^{(t)} - \gamma_{e} (x_i - m_{e}^{(t)}) \\
w_{j}^{(t+1)} &= w_{j}^{(t)} \quad j \neq c, \\
m_{j}^{(t+1)} &= m_{j}^{(t)}, \quad j \neq c, \quad j \neq r.
\end{align*}
\]

**Type 4. Local PCA Clustering (having quadratic boundaries between clusters):** \( C_j \) is a hyperplane passing through a point \( m_j \) with its normal direction \( w_j - m_j \) which is the minor axis of \( C_j \) with the minimum variance. Thus, \( \theta_j = \{m_j, w_j\} \). The error measure is \( \epsilon(x_i, \theta_j) = ||(w_i - m_{j})^T (x_i - m_{j})||^2 \).

Its adaptive implementation is quite similar to Type 3. More specifically, the part for updating \( m_j \) is still the same. However, updating for \( w_j \) are replaced by

\[
\begin{align*}
y_{e}(t+1) &= (x_i - m_{e}^{(t+1)}) - y_{e}(w_{e}^{(t)} - m_{e}^{(t+1)}) \\
w_{e}^{(t+1)} &= w_{e}^{(t)} + \gamma_{e} y_{e}[(x_i - m_{e}^{(t+1)}) - y_{e}(w_{e}^{(t)} - m_{e}^{(t+1)})] \\
m_{e}^{(t+1)} &= m_{e}^{(t)} - \gamma_{e} (x_i - m_{e}^{(t)}) \\
y_{j}(t+1) &= (x_i - m_{j}^{(t+1)}) - y_{j}(w_{j}^{(t)} - m_{j}^{(t+1)}) \\
w_{j}^{(t+1)} &= w_{j}^{(t)} \\
m_{j}^{(t+1)} &= m_{j}^{(t)}, \quad j \neq c, \quad j \neq r.
\end{align*}
\]
\[ w_i^{(t+1)} = w_r^{(t)} + \gamma_r[(x_i - m_i^{(t+1)}) - y_r (w_r^{(t)} - m_r^{(t+1)})] / ||w_r^{(t)} - m_r^{(t+1)}||, \]
\[ m_j^{(t+1)} = m_j^{(t)}, w_j^{(t+1)} = w_j^{(t)}, \quad j \neq c, \quad j \neq r. \]

**Type 5. Local Principal Subspace Clustering** (having quadratic boundaries between clusters): \( C_j \) is a \( r \)-dimensional subspace spanned by \( W_j = [w_j^{(1)}, \ldots, w_j^{(r)}] \) with the subspace’s origin located at a point \( m_j \). Thus, \( \theta_j = \{m_j, W_j\} \). The error measure is \( \varepsilon(x_i, \theta_j) = ||(I - P)(x_i - m_j)||^2 \) with \( P = W_j(W_j^TW_j)^{-1}W_j^T \) for a nonorthogonal matrix \( W_j \) or equivalently \( P = W_j^TW_j, \quad W_j^TW_j = I \) for an orthogonal matrix \( W_j \).

Its adaptive implementation is an extension of **Type 3** to higher dimension cases. Similarly, we use Oja subspace rule [8] and its anti-Hebbian variant for its updating:

\[ y_c = (W_c(t) - m_c^{(t+1)}[1, \ldots, 1])^T(x_i - m_i^{(t+1)}), \]
\[ W_c^{(t+1)} = W_c^{(t)} + \gamma_c[(x_i - m_i^{(t+1)}) - (W_c^{(t)} - m_c^{(t+1)}[1, \ldots, 1])y_c]y_c^T, \]
\[ y_r = (W_r^{(t)} - m_r^{(t+1)}[1, \ldots, 1])^T(x_i - m_i^{(t+1)}), \]
\[ W_r^{(t+1)} = W_r^{(t)} - \gamma_r[(x_i - m_i^{(t+1)}) - (W_r^{(t)} - m_r^{(t+1)}[1, \ldots, 1])y_r]y_r^T, \]
\[ m_j^{(t+1)} = m_j^{(t)}, W_j^{(t+1)} = W_j^{(t)}, \quad j \neq c, \quad j \neq r. \]  

**Type 6. Nonlinear Manifold Clustering:** \( C_j \) is represented by some nonlinear manifold and \( \varepsilon(x_i, \theta_j) \) is some kind of projection error to this manifold.

**Type 7. Hybrid Clustering:** \( C_1, \ldots, C_J \) and its related error are not necessary to be represented in the same type, but can be a mixture of more than one of the above types.

Through the following Gibbs distribution

\[ P_j(x, \theta_j) = \frac{1}{Z_j} \exp(-\lambda_j \varepsilon(j, \theta_j)), \quad \lambda_j > 0. \]  

we can link the Multi-Sets Modeling to the finite mixture eq.(4). Moreover, in the special case that \( Z_j, \lambda_j \) are the same for all \( j \) or if we can approximately ignore the difference between \( Z_j, \lambda_j \) for different \( j \). Then, the above discussed RPCL learning algorithms for each type of multi-sets are the same as the **Type B RPCL** learning in Sec.2.

**4. Experiments**

In the experiments, as shown in Fig.1, 2-dimensional data sets with different shapes and degree of overlapping are used. They all have four clusters and each contains 500 data points. The clusters in data set 1 and 2 are very clearly separated with the later one contains ellipse-shaped clusters. For data set 3, there are two ellipse shaped clusters overlapping together on the left and those in data set 4 also similar but with overlapping clusters on each side. In this paper, only the results on comparison with (i) the original RPCL eq.(3) (denoted by **Point case** since each cluster is simply presented by its center point), (ii) the **Type A RPCL** learning eq.(3) (simply denoted by **Type A**), eq.(8) & eq.(10) and (iii) the **Type B RPCL** learning eq.(3), eq.(10) & eq.(10) (simply denoted by **Type B**), are considered.

(1) **Cluster Number Detection** In this part, the cluster number detection ability of the algorithms are studied. For all the tests, five units are initialized. All the mean vectors randomly initialized with range [-1,1], and all the covariance matrices (if any) are positive diagonal random matrix with entries ranged in [0,1]. The selected mean movements (learning paths of mean vectors) by the original RPCL and **Type B RPCL** on the data set 2 are shown in Fig. 2 and Fig.3. The successful rates on four data sets within ten tests are summarized in Table 1. It can be seen that although all the algorithms work well for Data set 1 and Data set 2, as the overlap increases, the original RPCL degenerates quickly and usually will fail. Moreover, **Type B RPCL** performs the best and can always success.

(2) **The Confusion Matrices of the successful clustering** In this part, assume that we already know the number of clusters and fix the number of neurons on the correct number \( k = 4 \). The confusion matrices on clustering results on the four data sets by the three algorithms are shown in Tables 3, 4, 5 & 6 respectively. The averaged percentage of correctness in clustering each data set are shown in Table 2. It can be observed again, that the performance of the original RPCL degenerates considerably as the overlaps between clusters increases. However, **Type A RPCL** and **Type B RPCL** both work very well even for the very strongly overlapped Data set 4, and there is no obvious differences between the performance of **Type A** and **Type B**. It means that both types of RPCL work well if the number of cluster is set correctly.

**5. Conclusions**

For clusters of complicated shapes with strong overlapping, the performance of original RPCL algorithm degenerates considerably, however both **Type A** and **Type B RPCL** work well and improved the original RPCL considerably. Moreover, the **Type B RPCL** is the best in automatic selection of correct number of clusters.
The author would like to thank Mr. Wing-kai Lam for the help in preparing Figs.1-3 and Tabs.1-6.
